Abstract—In WDM networks, survivable routing and wavelength assignment (SRWA) involves assigning link-disjoint primary and backup lightpaths. In the on-line SRWA problem, a sequence of requests arrive and each request is either accepted or rejected based only on the input sequence seen so far. For special networks, we establish on-line algorithms with constant and logarithmic competitive ratios. It is not possible to obtain good competitive ratios in general topologies. Hence, we propose heuristic schemes and evaluate their performance by way of simulations. The building blocks in these schemes are 2-approximation algorithms (MSA and EXA) that we establish for the minimum disruption link-disjoint paths (MDLDP) problem. These approximations require far less memory and computation time than the best-known exact solution of the MDLDP problem. We use these three algorithms as heuristics for the on-line SRWA problem for infinite and finite duration requests and we show that, in terms of on-line performance, our algorithms do as well as (even at times better than) the exact algorithm of the MDLDP problem. We also provide an exact ILP formulation to solve the infinite duration off-line SRWA problem.

I. INTRODUCTION

In optical networks employing wavelength-division multiplexing (WDM), the enormous capacity of a fiber is divided into several non-overlapping wavelength channels that can transport data independently. These wavelength channels make up lightpaths, which are used to establish point-to-point optical connections that may span several fiber links without using routers. In wavelength-selective WDM networks, a lightpath connection between a source and a destination must have the same wavelength in all links along its route. In wavelength-interchanging WDM networks, the nodes have the capability to convert a wavelength at an incoming link to a different one at an outgoing link. Unfortunately, the high price of wavelength converters makes them less desirable. Therefore, in this paper we only focus on wavelength-selective networks.

In WDM networks, provisioning lightpaths involves not only routing, but also wavelength assignment and this problem is referred to as the routing and wavelength assignment (RWA) problem. Due to the tremendous amount of data transported, survivability, which is the ability to reconfigure and re-establish communication upon failure, is indispensable in WDM networks. Since in reality not all the links fail at the same time, we consider the single-link failure model, where at most a single link fails at any given time. The survivable routing and wavelength assignment (SRWA) problem is to assign, given a set of lightpath requests, link-disjoint primary and backup lightpaths to each request so that the total number of accepted requests is maximized.

For a single request, the SRWA problem can be solved with Suurballe’s algorithm [9], if the primary and backup lightpaths use the same wavelength (for different wavelengths, it is NP-complete). But, in practice, lightpaths requests arrive over time and the decision to accept or reject a request is made without any knowledge of future requests, yet maintaining the goal to maximize the total number of accepted requests. This version of the SRWA problem is called on-line SRWA. An algorithm is said to be an on-line algorithm if, for any arbitrary input sequence \( \sigma \), at any point in the sequence a decision is made based on the input seen so far and without any knowledge of the future. On the other hand, an off-line algorithm is assumed to know the whole input sequence. Thus, the performance of an on-line algorithm \( A \) can at best be as good as an optimal, but usually non-implementable, off-line algorithm \( OPT \).

Definition 1: An on-line algorithm \( A \) is said to be \( \rho \)-competitive if for any input sequence \( \sigma \),

\[
B(A, \sigma) \geq \frac{1}{\rho} B(OPT, \sigma)
\]

where \( B(X, \sigma) \) is the number of accepted requests by algorithm \( X \) for the input sequence \( \sigma \). The smallest such \( \rho \) is called the competitive ratio of the algorithm.

In Section II, we provide algorithms for the on-line SRWA problem with constant and logarithmic competitive ratios for specific networks. In Section III, we introduce rerouting of lightpaths to improve the practical performance of on-line routing. To this end, we discuss a related problem called the minimum disruption link-disjoint paths (MDLDP) problem and provide two 2-approximation algorithms for solving it. An algorithm is a 2-approximation algorithm for MDLDP if for any request, the number of lightpaths rerouted by its solution is at most twice that of the optimal algorithm. In Sections IV and V, we employ these algorithms as heuristics to solve the on-line SRWA with rerouting problem for requests of infinite and finite duration, respectively.

II. ON-LINE SRWA

The on-line survivable routing and wavelength assignment (SRWA) problem is defined as follows.

Problem 1: On-line SRWA: The physical optical network is modeled as an undirected graph \( G(N, \mathcal{L}) \), where \( N \) is
requests. For each request \((i \in \sigma)\) is represented by \((s_i, t_i)\), where \(s_i, t_i \in N\) are its source and destination nodes, respectively. The on-line SRWA problem is to allocate for each request link-disjoint primary and backup lightpaths such that (1) the same wavelength is used on all links of the primary and backup lightpaths, (2) no two lightpaths having the same wavelength can share a link, and (3) the decision to accept or reject a request is based only on the input sequence seen so far. The objective is to maximize the number of accepted requests.

Before addressing the on-line SRWA problem, we consider the on-line SRWA problem without survivability (on-line RWA) and other related problems that have been studied in the literature.

**Problem 2: On-line Maximum Disjoint Paths (MDP)**

**Problem:** Given a graph \(G(N, L)\) and a sequence of requests. For each request \((s_i, t_i)\), find a path \(P_i\) that connects \(s_i\) and \(t_i\) such that no two paths share the same link. The objective is to maximize the total number of accepted requests.

The MDP problem is NP-complete [5]. Since lightpaths on the same wavelength are not allowed to share a link, the on-line MDP problem is equivalent to the on-line RWA problem with \(W = 1\). Awerbuch et al. [3] have shown that if there is a \(\rho\)-competitive algorithm for the on-line MDP problem, then a \((\rho + 1)\)-competitive algorithm can be obtained for the on-line RWA problem by employing the on-line MDP algorithm on each wavelength.

The on-line MDP problem has been widely studied in the literature. The \(\Omega(N^2)\), where \(a = \frac{2}{\rho}(1 - \log_4 3)\) lower bound given by Bartal et al. [4] for randomized algorithms shows that it is not possible to find a good competitive ratio for general networks. In fact, most of the work in the literature has been restricted to special networks such as lines, trees, lattices, tree of rings, etc.

**Problem 3: On-line \(k\) Maximum Disjoint Paths (k-MDP)**

**Problem:** Given are a graph \(G(N, L)\) and a sequence of requests. For each request \((s_i, t_i)\), find \(k\) link-disjoint paths \(P_{i1}, \ldots, P_{ik}\) that connect \(s_i\) and \(t_i\) such that no two paths of different requests share the same link. The objective is to maximize the total number of accepted requests.

A simple upper-bound of any non-preemptive on-line algorithm for \(k\)-MDP is \(O(\frac{1}{\rho})\). Suurballe’s [9] algorithm \((k = 2)\) has a competitive ratio equal to this upper-bound. For example in Figure 1, if the input sequence is \((s, t)\) followed by \((s, a_1), (a_1, a_2), \ldots, (a_k, t), (s, b_1), (b_1, b_2), \ldots, (b_k, t)\) and all links have equal cost, the on-line algorithm accepts \(O(N)\) requests (i.e., all except the first), but the off-line algorithm accepts only the first two requests. Since in this example \(L = O(N)\), the competitive ratio is of the same order as the upper-bound.

Using the same argument provided by Awerbach et al. [3], a \((\rho + 1)\)-competitive algorithm for the on-line SRWA problem \((W > 1)\) can be derived from a \(\rho\)-competitive algorithm of the on-line 2-MDP problem. Hence, in the remainder of this section, we provide algorithms and corresponding competitive ratios for the on-line 2-MDP problem, which forms the basis for the on-line SRWA problem, in star-of-rings, tree-of-rings, and lattice networks. Even though these are simple networks, not only do they help us gain insight into the problem, but they are also used in real networks (e.g., the SURFnet network in the Netherlands resembles a star-of-rings).

### A. Star-of-rings network

**Algorithm 1** Star\_Alg\((G, s, t)\)

- Accept a request if it is the first request so far that uses the ring(s) to which the source and destination nodes belong.
- Reject, otherwise.

**Star\_Alg\((G, s, t)\)** is 2-competitive if the number of rings is greater than 1. For a single ring, it is optimal. Figure 2 shows an example where Star\_Alg\((G, s, t)\) is 2-competitive for the input sequence \((a, b), (b, c), (a, d)\). In this example, the on-line algorithm accepts only the first request, while the off-line algorithm accepts the last two requests.

![Fig. 2. A star of rings containing four rings.](image)

**Algorithm 2** Tree\_Alg\((G, s, t)\)

- Replace each ring by a single link so that the whole tree of rings is substituted by the underlying tree topology.
- Each 2-MDP request in the tree of rings is equivalent to a corresponding MDP request in the underlying tree.
- Use the algorithm of Awerbach et al. [2], which has \(O(\log N)\) competitive ratio for a tree of \(N\) nodes, to solve the on-line MDP problem.

From [2], it follows that Tree\_Alg\((G, s, t)\) is \(O(\log \Upsilon)\)-competitive, where \(\Upsilon\) is the number of rings.

1http://www.surfnet.nl/en
C. Lattice network

The $O(\log N)$-competitive algorithm given by Kleinberg and Tardos [6] for the on-line MDP problem can, with a slight modification, be used for solving the on-line 2-MDP problem with an $O(\log N)$-competitive ratio. We have described the modified algorithm in detail in a technical report [12].

III. On-line SRWA with Rerouting

In Section II, we provided algorithms for the on-line 2-MDP problem in specific networks, which can be used to derive corresponding algorithms for the on-line SRWA problem. Unfortunately, it is not possible to attain a good competitive ratio for general networks [4]. In this section, we explore the idea of rerouting lightpaths to improve performance. Although rerouting does not improve the competitive ratio, we show through simulations that it can increase the acceptance rate considerably. In wavelength-selective WDM networks, a rerouting procedure may be path rerouting (i.e., changing the route of a lightpath while keeping the wavelength), wavelength rerouting (i.e., changing the wavelength while keeping the path) or a combination of both. Compared to path rerouting, wavelength rerouting does not need extra path computation (as it retains the same path), facilitates control and, if the rerouted lightpath is moved to a vacant route on another wavelength, it incurs less traffic disruption [7]. We therefore focus on wavelength rerouting.

Generally, the wavelength rerouting problem is NP-complete [7]. It consists of solving the three possible scenarios presented below. The second and the third scenarios make the problem hard to solve. Figure 3 shows the different scenarios. The labels on the links represent already existing lightpaths.

1) When the lightpaths to be rerouted are on the same wavelength, they can be moved to vacant wavelengths in parallel without any conflict (since they do not share links). For example, in Figure 3(a), a new lightpath from node 1 to 5 can be accepted on wavelength $w_2$ by rerouting lightpath $p_3$ to $w_1$ and $p_4$ to $w_3$ in parallel.

2) When the lightpaths are on different wavelengths, moving to vacant wavelengths can be done sequentially while checking for conflicts. For example, in Figure 3(b), a new lightpath from node 1 to 5 can be accepted on $w_1$ by first rerouting $p_4$ to $w_3$ and then $p_1$ to $w_2$.

3) Moving to a vacant wavelength may not be sufficient, and it may be necessary to swap the wavelengths of lightpaths. For example, in Figure 3(c), a new lightpath from node 1 to 4 can be accepted on $w_2$ by swapping the wavelengths of $p_2$ and $p_3$.

In the literature and the remainder of this paper, the term wavelength rerouting is used to refer to the reduced problem, i.e., assigning a lightpath by moving existing lightpaths on the same wavelength to vacant wavelengths in parallel. Xue [11] has shown that this problem can be solved in $O(WN \log N + WL)$ time.

On-line SRWA with wavelength rerouting involves assigning link-disjoint primary and backup lightpaths for new requests by rerouting, if necessary, already existing lightpaths. When rerouting lightpaths, the number of lightpaths rerouted should be kept to a minimum. This leads us to consider the minimum-disruption link-disjoint paths (MDLDP) problem. The MDLDP problem is NP-complete when the primary and backup lightpaths use different wavelengths. However, it is polynomially solvable for the same wavelength [10]. We consider the polynomially-solvable version.

Problem 4: Minimum Disruption Link-Disjoint Paths (MDLDP): The physical optical network is modeled as an undirected graph $G(N, L)$, where $N = |N|$ and $L = |L|$. Each fiber link has a set $\Lambda = \{w_1, w_2, \ldots, w_M\}$ of $W$ wavelengths. Given a request $i$, the MDLDP problem is to allocate on the same wavelength link-disjoint primary and backup lightpaths for request $i$, while minimizing the number of lightpaths to be rerouted.

Wan and Liang [10] provided an $O(WL^5 \log N)$ exact algorithm for solving the MDLDP problem. We refer to this algorithm as $WLA$. $WLA$ has a very high running time and requires a large amount of memory. This makes it less suitable, especially in an on-line setting where the algorithm has to be invoked whenever a new request arrives. We propose two 2-approximation algorithms with considerably less running times and memory requirements.

A. 2-Approximation Algorithms for MDLDP

We provide two 2-approximation algorithms for MDLDP: $MSA$ and $ESA$. $MSA$ is a modified version of Suurballe’s algorithm [9] with a running time of $O(WN \log N + WL)$ and $ESA$ is an extended algorithm with a running time of $O(WN^2 \log N + WNL)$. This is a significant reduction from the $O(WL^5 \log N)$ running time of the exact $WLA$ algorithm with at most twice as much lightpaths being rerouted.

In our notation, we use $p$ to represent a lightpath and $P$ to represent any path. A lightpath on wavelength $w_i$ is said to be reroutable, if and only if all of its links are free on at least one other wavelength $w_j$, i.e., no lightpath is using these links on $w_i$. A path $P$ from $s$ to $t$ is said to traverse a lightpath $p$ if it shares at least one link with $p$. Let $P_k$ be the set of lightpaths on wavelength $w_k$; $P'_k \subseteq P_k$ be the set of reroutable lightpaths on wavelength $w_k$; $P''_k = P_k \setminus P'_k$ be the set of non-reroutable lightpaths on wavelength $w_k$; and $\Lambda_{(i,j)}$ be the set of free wavelengths on fiber link $(i,j)$.

We identify $W$ subgraphs, $G_k = G(N, L_k)$, $L_k = \{(i,j) \in$
\[ L | w_k \in \Lambda_{(i,j)} \text{ or } \exists p \in P_k^i \text{ such that link } (i,j) \text{ belongs to lightpath } p. \] The cost of a link \((i,j)\) in subgraph \(G_k\) is \( \text{cost}_k(i,j) = \epsilon \) if \((i,j)\) is a free link, where\(^2\) \( 2N\epsilon < 1; \text{cost}_k(i,j) = 1 \) otherwise. However, the cost \( \text{cost}_k(P) \) of a path \( P \) in subgraph \( G_k \) is the sum of the cost of its free links and the number of distinct reroutable lightpaths traversed by \( P \), i.e., multiple links belonging to a lightpath are counted only once. Thus, the shortest path between two nodes traverses the minimum number of reroutable lightpaths. Note that any lightpath that is traversed by the shortest path is encountered only once, i.e., in a single segment (of possibly multiple links).

Algorithm 3 MSA(\(G, s, t\))

1) For each \( G_k, k = 1, \ldots, W \)
   a) In graph \( G_k \), find the shortest path from \( s \) to \( t \).
   b) Graph \( G'_k \) is obtained by directing each link \((i,j)\) of the shortest path from \( s \) to \( t \), setting the cost of the free links on the shortest path as \( \text{cost}_k(j,i) = -\text{cost}_k(i,j) \) and the cost of all links of lightpaths that are traversed by the shortest path to zero.
   c) Find the shortest path from \( s \) to \( t \) in \( G'_k \).
   d) If the shortest path exists in \( G'_k \), remove all the overlapping links between the two paths in \( G_k \) to obtain the solution.

2) Choose the best solution among all wavelengths.

In Step 1a of the MSA algorithm, we find the shortest path from \( s \) to \( t \) (using an algorithm such as the one given in [11]). In Step 1b, the cost of all links belonging to lightpaths traversed by the shortest path is set to zero so that these links are preferred in the second path and the lightpaths are not counted twice. Similarly, the cost of free links on the shortest path is set to \(-\epsilon\).

Theorem 1: MSA is a 2-approximation algorithm for the MDLDP problem.

**Proof:** Since the best solution is chosen after independently considering each wavelength, it suffices to consider only the wavelength that provides the best solution. Assume that for this wavelength, given that a solution of MSA that traverses a total of \( K \) lightpaths, there is an optimal solution that traverses less than \( \frac{K}{2} \) lightpaths, which would violate the claim of 2-approximation. Our intention is to prove that the assumption is wrong.

Let \( \ell(P) \) represent the number of lightpaths traversed by a path \( P \) and \( \ell(P_1, P_2) \) represent the number of distinct lightpaths traversed by paths \( P_1 \) and \( P_2 \), where \( \ell(P_1, P_2) \leq \ell(P_1) + \ell(P_2) \).

Let \( \{P_1^*, P_2^*\} \) be the optimal solution. In MSA, let \( P_1 \) be the first shortest path that is obtained in Step 1a and \( P_2 \) be the second shortest path that is obtained in Step 1c.

Let \( Q \) be the set of alternating lightpaths of the optimal solution \( \{P_1^*, P_2^*\} \), i.e., lightpaths with segments in both \( P_1^* \) and \( P_2^* \). Let \( S \) be the set of links of lightpaths \( p \in Q \).

\[ \ell(P_1^*, P_2^*) < \frac{K}{2} \] implies that \( \ell(P_1^*) < \frac{K}{2} \) and \( \ell(P_2^*) < \frac{K}{2} \). Hence, the first shortest path returned by MSA must have \( \ell(P_1) < \frac{K}{2} \). Since \( \ell(P_1, P_2) = K \), the second shortest path returned by MSA should have \( \ell(P_2) > \frac{K}{2} \). However, MSA can find a path \( P_2 \) from the set of links of \( P_1^*, P_2^* \) and \( S \). If \( P_2 \) also contains any of these links, they are redirected in Step 1b of MSA and are assigned a cost of zero. Since no new lightpaths are added \( \ell(P_2) < \frac{K}{2} \), which is a contradiction.

The 2-approximation is attained in the worst case when \( \ell(P_1) = \ell(P_2) = \ell\{P_1^*, P_2^*\} \) and \( P_1 \) and \( P_2 \) do not have common lightpaths as shown in Figure 4(a). \( P_1 = \{s, 3, t\}, P_2 = \{s, 4, t\}, P_1^* = \{s, 1, 2, t\}, \) and \( P_2^* = \{s, 5, 6, t\}; \ell(P_1, P_2) = 2 \) and \( \ell\{P_1^*, P_2^*\} = 1 \).

![Fig. 4. (a) A worst case for MSA that leads to a 2-approximation and (b) an example where ESA fails.](image_url)

The example in Figure 4(a) can exactly be solved if \( P_1 \) leaves the source node through node 1 or node 5. We can achieve this by extending the MSA algorithm so that it checks the shortest path through any given node \( u \in \mathcal{N} \setminus \{s, t\} \). This is exactly what our extended algorithm ESA does. As it can be seen later in Section III-C, ESA has a significantly improved performance in solving the MDLDP problem. But, it fails for cases like the one in Figure 4(b), where \( P_1 = \{s, 1, 3, t\}, P_2 = \{s, 2, 3, 5, t\}, P_1^* = \{s, 1, 3, 4, t\}, \) and \( P_2^* = \{s, 2, 3, 5, t\}; \ell(P_1, P_2) = 3 \) and \( \ell\{P_1^*, P_2^*\} = 2 \).

In ESA, for each node \( u \in \mathcal{N} \setminus \{s, t\} \), we find link-disjoint paths from \( s \) to \( t \), where the first path is forced to go through \( u \). In Step 1a-ii, the cost of all links on \( P_{s-u} \) and all links belonging to lightpaths on \( P_{u-t} \) (except those of the lightpath on the last link, if there is any) is set to infinity. This is to prevent the same links from being used again in \( P_{u-t} \) and to make sure that any lightpath in \( P_{u-t} \) is traversed in at most one segment. For the lightpath on the last link, since our interest is to find the shortest path from \( s \) to \( t \) through \( u \), it can still be encountered just after \( u \). Therefore, its links, except those in \( P_{u-t} \), will have a cost of zero. In Step 1a-iii, the shortest path from \( u \) to \( t \) is found. If \( P_{s-u} \) and \( P_{u-t} \) share nodes, then the algorithm does not proceed to finding the second shortest path. Instead, it skips to searching for the solutions of the remaining paths. Once the path through \( u \) is found by concatenating \( P_{s-u} \) and \( P_{u-t} \), the links on this path are directed from \( t \) to \( s \) in Step 1a-iv. In Step 1b, all the solutions are compared and the one that traverses the minimum number of lightpaths is chosen. If there are multiple solutions that traverse the same number of lightpaths, the one with the
Algorithm 4 ESA($G,s,t$)

1) For each $G_k$, $k = 1,\ldots,W$
   a) For each node $u \in \mathcal{N}\setminus\{s,t\}$:
      i) In graph $G_k$, find the shortest path $P_{s-u}$ from $s$ to $u$.
      ii) Graph $G'_k$ is obtained from $G_k$ by setting the cost of all links on $P_{s-u}$ and each link belonging to lightpaths on $P_{s-u}$ to infinity except for links of the lightpath (if any) in the last link of $P_{s-u}$. For the lightpath in the last link, all its links except the ones in $P_{s-u}$ will have a cost of zero.
      iii) In graph $G'_k$, find the shortest path $P_{u-t}$ from $u$ to $t$. If $P_{s-u}$ and $P_{u-t}$ share nodes, go to Step 1a-i if there are remaining nodes whose shortest paths have not been found, otherwise go to Step 1b. If $P_{s-u}$ and $P_{u-t}$ do not share nodes, the shortest path through $u$ is found by concatenating the two.
      iv) Graph $G''_k$ is obtained from $G_k$ by directing each link $(i,j)$ along the shortest path from $t$ to $s$. The cost of free links on the shortest path is set to $\text{cost}_{sk}(i,j) = -\text{cost}_{tk}(i,j)$ and the cost of all links belonging to lightpaths on the shortest path is set to zero.
      v) In graph $G''_k$, find the shortest path from $s$ to $t$.
      vi) If the shortest path exists, remove all the overlapping links.
   b) Choose the best solution among all nodes.

2) Choose the best solution among all wavelengths.

The total running time of the reroutability update procedure is $O(N^2 + NW)$. We employ this procedure when solving the on-line SRWA problem using the MDLDP algorithms.

C. Simulation Study

We proceed to compare our 2-approximation algorithms (MSA and ESA) with the exact algorithm (WLA) in solving the MDLDP problem. In order to simulate a wide range of possibilities, we generate dynamic traffic, where requests arrive according to a Poissonian distribution (arrival rate $r$) with exponential holding times of mean 1. For each request, we record the results of our algorithms in comparison to WLA. The approximation ratio represents the ratio of the number of lightpaths traversed by an approximation algorithm to the number of lightpaths traversed by WLA. It is averaged for all accepted requests over 10 iterations, each 5000 requests. The source and destination nodes are randomly selected with all nodes having equal probability of being selected.

We consider three networks: an ARPANET network (Figure 5), an Erdős-Rényi random network ($N = 50$, link density $\alpha = 0.2$, i.e., the average total number of links is $\alpha \cdot O(N^2)$), and a $7 \times 7$ lattice network, each with $W = 10$ wavelengths. In all our simulations, the approximation ratio attained by ESA never exceeded 1.00004. The approximation ratios of both ESA and MSA in comparison to the exact algorithm were much smaller than 2. Table I shows the average simulated
approximation ratios of MSA, in terms of the number of lightpaths rerouted, when compared to WLA, which returns the exact number for a given request.

In Sections IV and V, we use the aforementioned MDLDP algorithms to heuristically solve infinite and finite duration on-line SRWA, respectively. For each case, we compare the performances of MSA, ESA and WLA.

IV. INFINITE DURATION ON-LINE SRWA
In the infinite duration on-line SRWA problem, lightpaths stay indefinitely once they arrive. The off-line SRWA problem, where all the requests are known beforehand, can be described as a network flow problem. For this, we provide ILP formulations under two cases: case 1, when both the primary and backup lightpaths have to use the same wavelength and case 2, when they can use different wavelengths.

Indices:
- \( i = 1, \ldots, F \) ID of requests (\( F \) in total)
- \( w = 1, \ldots, W \) ID of wavelengths
- \( N(u) \) Set of nodes adjacent to node \( u \)

Variables (integers):
- \( \gamma_{i,w,u,v} \) is 1 (or -1 depending on the flow direction) if the primary or backup lightpaths of request \( i \) use wavelength \( w \) on link \((u,v)\) \( \in \mathcal{L} \); 0 otherwise.
- \( x_{i,w} \) is 1 if request \( i \) is accepted and uses wavelength \( w \); 0 otherwise.
- \( \gamma_{i,w,s_t} \) is 1 if neither the primary nor the backup lightpaths of request \( i \) are on wavelength \( w \); 1 if either the primary or the backup lightpath of request \( i \) is on wavelength \( w \); 2 if both the primary and the backup lightpaths of request \( i \) are on wavelength \( w \).

Objective:
Maximize the number of accepted requests.

\[
\text{Maximize: } \sum_{i=1}^{F} y_i
\]

Constraints
- **Antisymmetry constraints:** Since the graph is undirected, the flow is in both directions.
- \( \gamma_{i,w,u,v} = -\gamma_{i,w,v,u} \quad \forall (u,v) \in \mathcal{L} ; 1 \leq i \leq F ; 1 \leq w \leq W \).
- **Conservation constraints:** If a given node is not the source or destination of a given request, then any flow related to the request that enters the node has to leave the node.
- \( \sum_{v \in N(u)} \gamma_{i,w,u,v} = 0 \quad \forall u \in \mathcal{N}\{s_t, t_t\} ; 1 \leq i \leq F ; 1 \leq w \leq W .
- **Capacity constraints:** Only a single lightpath can use a given wavelength on a certain link.

\[
\sum_{i=1}^{F} \gamma_{i,w,u,v} \leq 1 \quad \forall (u,v) \in \mathcal{L} ; 1 \leq w \leq W .
\]

**Disjointedness constraints:** The primary and the backup lightpaths of a request should be link-disjoint.

\[
\sum_{w=1}^{W} \gamma_{i,w,u,v} \leq 1 \quad \forall (u,v) \in \mathcal{L} ; 1 \leq i \leq F .
\]

Equations
For Case 1: Lightpaths of a request on a given wavelength.
- \( \sum_{v \in N(s_t)} \gamma_{i,w,s_t,v} = 2 \cdot x_{i,w} \quad 1 \leq i \leq F ; 1 \leq w \leq W .
- \sum_{v \in N(t_t)} \gamma_{i,w,v,t_t} = 2 \cdot x_{i,w} \quad 1 \leq i \leq F ; 1 \leq w \leq W .

For Case 2: Lightpaths of a request on a given wavelength.
- \( \sum_{v \in N(s_t)} \gamma_{i,w,s_t,v} = x_{i,w} \quad 1 \leq i \leq F ; 1 \leq w \leq W .
- \sum_{v \in N(t_t)} \gamma_{i,w,v,t_t} = x_{i,w} \quad 1 \leq i \leq F ; 1 \leq w \leq W .

An accepted request has link-disjoint primary and backup lightpaths.

\[
\sum_{w=1}^{W} x_{i,w} = 2y_i \quad 1 \leq i \leq F .
\]

Solving the given ILP formulation for large networks and high number of requests is not feasible. Therefore, we use the algorithms of the MDLDP problem to solve the on-line SRWA problem sequentially. Clearly, this approach will not guarantee an optimal solution. However for small networks, we show that the results obtained by these algorithms are close to the optimal off-line solution (given by the ILP for case 2), which does not need rerouting. Tables II and III show comparisons, in terms of the number of rejected requests, of our algorithms (MSA and ESA), WLA and without
rerouting (W/R) against the optimal ILP formulation for small random networks with link density α (N = 10 with 20 requests and N = 12 with 30 requests) and W = 4. We observe that rerouting performs better (though marginally, since the network is small and the number of requests are few) than without rerouting and our algorithms perform as good as (and at times better than) WLA.

<p>| Number of rejected requests for N = 10 and 20 requests. |

V. Finite Duration On-Line SRWA

Finite duration SRWA requests arrive to and depart from the network over time. Thus, any two lightpaths can share requests as long as they do not overlap in time. We use the algorithms of MDLDP as heuristics to solve the finite duration on-line SRWA problem.

We use the same scenarios as in Section III-C for our simulations. Figures 6-11 show comparisons of the performance of our algorithms (MSA and ESA) with WLA in terms of the percentage of rejections. The given results are (a) for different number of requests with a constant arrival rate, and (b) for different arrival rates with a constant number of requests. A comparison of these algorithms with the case of no rerouting (W/R) shows that rerouting of lightpaths decreases the percentage of rejections significantly. In addition, we observe that both MSA and ESA perform similarly to WLA, which has much higher running time and memory requirements. The need to have a small running time becomes more pronounced in an on-line setting, where the algorithm has to be invoked repeatedly whenever a request arrives.

VI. Conclusions

In WDM optical networks, where lightpaths carry a tremendous amount of data, survivability is of paramount importance. In practice, lightpath requests arrive over time and a decision on whether to accept or deny a request should be made without any knowledge of the future requests. Therefore, it is necessary to have an on-line solution scheme with good performance to deal with survivable routing and wavelength assignment (SRWA). In this paper, we have studied on-line
SRWA and have provided constant and logarithmic competitive ratios for special networks. For general networks, it is not possible to have algorithms with good competitive ratios. Since the competitive ratio reflects a worst-case performance, we considered lightpath rerouting, which generally improves the acceptance rate, but not the competitive ratio. To serve this purpose, we studied the Minimum Disruption Link-Disjoint Paths (MDLDP) problem, for which we provided two 2-approximation algorithms: MSA and ESA. We have shown through simulations that these algorithms perform close to the best-known exact algorithm for MDLDP, which incurs a very high time-complexity. We subsequently applied all considered MDLDP algorithms as heuristics for infinite and finite duration on-line SRWA. For infinite duration SRWA, these algorithms performed close to the optimal off-line solution (for which we provided an ILP formulation). For finite duration SRWA, we considered Poissonian distributed input sequences with exponential holding times. In these scenarios, our algorithms performed as good as (and at times even better than) the exact algorithm of the MDLDP problem, but in a much faster time. These findings suggest that our algorithms are more suitable for dealing with the (on-line) SRWA problem.
